COVID-19 Drug Therapy

Tim Smith, PharmD, BCPS; Jennifer Bushek, PharmD; Aimée LeClaire, PharmD, BCPS; Tony Prosser, PharmD

Clinical Drug Information | Clinical Solutions

What’s been updated:

- Colchicine updated with data from a single-center cohort of adults hospitalized with COVID-19 pneumonia and acute respiratory distress syndrome
- Interleukin-6 (IL-6) receptor antagonists updated with data from a study evaluating efficacy of subcutaneous tocilizumab in treating severe COVID-19-related cytokine release syndrome
- Favipiravir updated with data from a multicenter, randomized, Phase II/III study of adults hospitalized with moderate COVID-19 pneumonia

Highlights:

- There are no specific therapies approved by the U.S. Food and Drug Administration (FDA) for severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2), the virus that causes coronavirus disease 2019 COVID-19. Multiple agents are under investigation based on in vitro activity (against SARS-CoV-2 or related viruses) and on limited clinical experience. Efficacy has not been established for any drug therapy.
- **Antimicrobials with potential activity against SARS-CoV-2:**
  - Remdesivir – Investigational antiviral available under an FDA Emergency Use Authorization (EUA); several large clinical trials are underway with preliminary data suggesting clinical benefit.
  - Chloroquine – *In vitro* and limited early clinical data suggested potential benefit; FDA EUA revoked due to lack of data to support efficacy.
  - Hydroxychloroquine – *In vitro* and limited early clinical data suggest potential benefit; FDA EUA revoked due to lack of data to support efficacy.
  - Lopinavir; Ritonavir – Preclinical data suggested potential benefit; however, more recent data failed to confirm.
  - Favipiravir – Broad spectrum investigational antiviral; licensed in other countries for treatment of influenza.
• **Adjunctive / supportive care:**
  - Anticoagulation – Venous thromboembolism prophylaxis with low molecular weight heparin (LMWH) recommended for all hospitalized patients.
  - Azithromycin – Early use based on theoretical mechanism and limited preliminary data as adjunct therapy; safety concerns and lack of efficacy data limits current use.
  - Bronchodilators – No routine role for inhaled bronchodilators in the management of COVID-19; metered-dose inhalers (MDI) preferred over nebulized therapy due to the risk of viral transmission.
  - Corticosteroids – Dexamethasone is recommended for patients who are mechanically ventilated or require supplemental oxygen; preliminary data found dexamethasone reduced deaths in patients with severe respiratory complications. Use of an alternative corticosteroid is recommended if dexamethasone is unavailable.
  - Colchicine – Limited data suggest potential benefit; use based on theoretical mechanism as adjunct therapy.
  - COVID-19 convalescent plasma – Investigational use is being studied.
  - Fibrinolytics – Severe COVID-19 infection is associated with coagulopathy; fibrin deposition in the pulmonary microvasculature is a causative factor in the development of ARDS.
  - Immunomodulating agents [Interleukin Receptor Antagonists, Janus Kinase (JAK) inhibitors] – Used in some protocols based on theoretical mechanisms and limited preliminary data as adjunct therapy.
  - Inhaled pulmonary vasodilators – No evidence for routine in acute respiratory failure; use may be considered in specific patients with acute respiratory distress syndrome (ARDS) as a temporizing measure.
  - NSAIDS – The FDA continues to investigate the use of NSAIDs; concern for potential worsening of COVID-19 symptoms has been suggested, but confirmatory clinical data is lacking.

According to the World Health Organization (WHO), the Centers for Disease Control and Prevention (CDC), the FDA, the National Institutes of Health (NIH), and the Infectious Diseases Society of America (IDSA) there are currently no medications or vaccines proven to be effective for the treatment or prevention of SARS-CoV-2. (1) (2) (3) (133) (161)

Generally, pharmacologic treatment is not recommended for young, healthy patients with mild symptoms and no underlying comorbid conditions.(12) (13)

**Understanding of the treatment of patients with COVID-19 is rapidly evolving. Information will continue to emerge regarding pharmacologic therapy for SARS-CoV-2 as clinical data are reported.**

**Antimicrobials with potential activity against SARS-CoV-2:**

**Remdesivir (GS-5734):**

Updated August 12, 2020
Copyright © 2020 Elsevier
• **Classification:** Investigational Nucleoside Analogue

• **Rationale for Use:** Remdesivir is a broad-spectrum antiviral with *in vitro* activity against coronaviruses.(10) (14) (38) (39) (41) (42) (43) (44)

• **Mechanism of Action:** Remdesivir is a monophosphoramidate prodrug of remdesivir-triphosphate (RDV-TP), an adenosine analog that acts as an inhibitor of RNA-dependent RNA polymerases (RdRps). Remdesivir-TP competes with adenosine-triphosphate for incorporation into nascent viral RNA chains. Once incorporated into the viral RNA at position i, RDV-TP terminates RNA synthesis at position i+3. Because RDV-TP does not cause immediate chain termination (i.e., 3 additional nucleotides are incorporated after RDV-TP), the drug appears to evade proofreading by viral exoribonuclease (an enzyme thought to excise nucleotide analog inhibitors).(10) (14) (38) (39) (41) (42) (43) (44) (45)

• **FDA Emergency Use Authorization (EUA):** (146)
  - Remdesivir is not an FDA-approved medication; however, the drug has been made available through an EUA. Similar restricted market authorizations have been issued by other nations.(168) (169)
  - Under the EUA, remdesivir can be used to treat suspected or laboratory confirmed COVID-19 in adults and children hospitalized with severe disease.
  - The EUA defines severe COVID-19 disease as patients with an oxygen saturation (SpO2) of 94% or less on room air, or requiring supplemental oxygen, or requiring mechanical ventilation or extracorporeal membrane oxygenation (ECMO).

• **Evidence / Experience:**
  - The NIH COVID-19 treatment guidelines recommend the use of remdesivir in hospitalized patients with severe COVID-19 as defined by the FDA EUA.(133)
    • Remdesivir therapy should be prioritized for hospitalized patients with severe COVID-19 who require supplemental oxygen BUT NOT on high-flow oxygen, noninvasive ventilation, mechanical ventilation, or ECMO; patients should receive 5 days of remdesivir with extensions for up to 5 additional days if no clinical improvement; if a patient progresses to requiring high-flow oxygen, ventilation, or ECMO while on remdesivir, continue remdesivir therapy.
    • In patients with severe COVID-19 requiring high-flow oxygen, noninvasive ventilation, mechanical ventilation, or ECMO, the NIH does not recommend for or against using remdesivir; patients should receive 10 days of remdesivir.
    • The NIH states that there is insufficient evidence to recommend for or against treatment in patients with mild or moderate COVID-19.
  - Preliminary data from a Phase 3 trial [Adaptive COVID-19 Treatment Trial (ACTT-1)] found remdesivir was superior to placebo in shortening recovery in hospitalized adults with COVID-19 and lower respiratory tract infection.(145)
    • The median time to recovery was 11 days in the remdesivir-treated group compared to 15 days in placebo group (rate ratio for recovery 1.32; 95% CI, 1.12 to 1.55, p less than 0.001).
    • Benefit was highest in the subgroup of hospitalized patients requiring supplemental oxygen but who were not mechanically ventilated or on ECMO (rate ratio for recovery 1.47; 95% CI, 1.17 to 1.84).
    • For the subgroup of patients on mechanical ventilation or ECMO, no difference was observed between remdesivir and placebo (rate ratio for recovery 0.95; 95% CI, 0.64 to 1.42).
• For the subgroup of patients with mild to moderate disease, no difference was observed between remdesivir and placebo (rate ratio for recovery 1.09; 95% CI, 0.73 to 1.62).

  ▪ Kaplan-Meier estimates of mortality by 14 days were 7.1% for the remdesivir group vs. 11.9% for the placebo group (HR 0.7; 95% CI, 0.47 to 1.04).

  o A randomized, double-blind, placebo-controlled, multicenter trial evaluating efficacy and safety of remdesivir in SARS-CoV-2 infected hospitalized adults (concurrent treatment with corticosteroids, interferons, and lopinavir; ritonavir was permitted).(150)

    ▪ No difference between remdesivir (n = 158) and placebo (n = 79) in the time to clinical improvement (median, 21 vs. 23 days; HR 1.23; 95% CI, 0.87 to 1.75). 28-day mortality was similar between remdesivir (14%) and placebo (13%) (95% CI, -8.1 to 10.3).

    ▪ Adverse events were reported in 66% of remdesivir patients and 64% of placebo patients. Remdesivir was stopped early in 12% of patients due to adverse events.

  o Randomized, open-label, Phase 3 trial comparing 5-day (n = 200) and 10-day (n = 197) courses of remdesivir in hospitalized patients with severe COVID-19 pneumonia (i.e., lung infiltrates and either receiving supplemental oxygen or an oxygen saturation of 94% or less on room air).(154)

    ▪ No significant difference between the 5-day and 10-day courses was observed in patients with severe COVID-19 not requiring mechanical ventilation.

      • At day 14, clinical improvement of at least 2 points on the 7-point ordinal scale was achieved by 65% in the 5-day group and 54% in the 10-day group.

      • Numerically, more patients were discharged from the hospital in the 5-day group than in the 10-day group (60% vs. 52%, respectively), and mortality was lower (8% vs. 11%, respectively).

      ▪ Of note, patients randomly assigned to the 10-day group had significantly worse clinical status at baseline (p = 0.02).

  o Preliminary data from open-label compassionate use in patients with severe disease was analyzed.(124)

    ▪ Clinical improvement, as defined by improvement in oxygen support, was reported in 36 of 53 patients (68%).

    ▪ Clinical improvement was less frequent in those receiving invasive ventilation and in patients 70 years or older.

  o A multicenter study compared efficacy of remdesivir versus standard of care alone in adults with severe COVID-19 using data from ongoing phase 3 trials (n = 312) and a retrospective cohort of patients (n = 818).(184)

    ▪ Patients had confirmed SARS-CoV-2 infection, were hospitalized, had oxygen saturation 94% or lower on room air or required supplemental oxygen, and had pulmonary infiltrates.

    ▪ At day 14, 74.4% of remdesivir patients had recovered versus 59% of patients receiving standard of care (aOR, 2.03; 95% CI, 1.34 to 3.09; p less than 0.01).

    ▪ At day 14, a clinical status of at least 2-points (or being discharged alive) was noted in 71.9% of remdesivir patients compared to 58.8% of patients receiving standard of care (aOR 1.64; 95% CI, 1.10 to 2.43; p = 0.001).
- At day 14, 7.6% of remdesivir patients had died versus 12.5% of patients receiving standard of care (aOR, 0.38; 95% CI, 0.22 to 0.68; p = 0.001).
  - Several clinical trials evaluating the efficacy of remdesivir in patients infected with SARS-CoV-2 are currently being conducted.(132)

Safety Concerns: (133) (146)
- Caution in patients with renal impairment due to formulation with sulfobutyl ether betacyclodextrin sodium (SBECd)
- Hypersensitivity and infusion-related reactions
- Risk for elevated hepatic enzymes

Chloroquine:

- Classification: Antimalarial
- Rationale for Use: Chloroquine has in vitro activity against SARS-CoV-2 and may have immunomodulating properties.(13) (14) (15) (17)
- Mechanism of Action: Mechanisms may include inhibition of viral enzymes or processes such as viral DNA and RNA polymerase, viral protein glycosylation, virus assembly, new virus particle transport, and virus release. Other mechanisms may also involve ACE2 cellular receptor inhibition, acidification at the surface of the cell membrane inhibiting fusion of the virus, and immunomodulation of cytokine release.(14) (15) (29) (30) (31) (32) (33)
- FDA Emergency Use Authorization (EUA): (66) (67) (158)
  - Chloroquine is not FDA-approved for the treatment of COVID-19.
  - On June 15, 2020, the FDA revoked the EUA for chloroquine stating that it is unlikely to be effective in treating COVID-19. Also, in light of ongoing serious cardiac adverse events and other serious side effects, the known and potential benefits of chloroquine no longer outweigh the known and potential risks for the authorized use.
  - The EUA was issued in March 2020 and previously stated that treatment was for adult and adolescent patients weighing 50 kg or more who were hospitalized with COVID-19.

Evidence / Experience:
- The NIH COVID-19 treatment guidelines recommend against the use of chloroquine for the treatment of COVID-19 outside of clinical trials. The NIH recommends against the use of high-dose, twice-daily chloroquine due to a higher risk of toxicities.(133)
- Pre-clinical data in vitro suggest chloroquine has activity has activity against SARS-CoV-2.(13) (14) (15)
- There have been reports of potential benefit in inhibiting the exacerbation of pneumonia patients with SARS-CoV-2 infection; however, specific data are not available.(13)
- Some protocols include recommendations for use.(12) (21) (22)
- Additional data regarding clinical efficacy for COVID-19 are being evaluated.(16) (31)

Safety Concerns: (46) (49)
- Use in COVID-19 patients outside of clinical trials or in a nonhospital setting is not recommended due to the potential for serious adverse events and drug interactions.(141)
- Risk of cardiac arrhythmias (e.g., QT prolongation)
  - Seriously ill patients with comorbidities have an increased risk of serious arrhythmias.(125)
- Avoid other QT prolonging agents whenever feasible.\(^{(125)}\)
- In a parallel, double-masked, randomized clinical trial (n = 81), two doses of chloroquine were analyzed (600 mg PO twice daily for 10 days vs. 450 mg PO twice daily on day 1 then 450 mg PO once daily for 4 days).\(^{(126)}\)
  - The high-dose group had a higher incidence of QT interval greater than 500 milliseconds (18.9%) compared with the low-dose group (11.1%); therefore, the study was unmasked and all patients were reverted to the low-dose group.
  - Risk of retinal damage, especially with long term use
  - Caution in patients with G6PD deficiency
  - Caution in diabetics
  - Significant drug interactions

**Hydroxychloroquine:**
- **Classification:** Antimalarial
- **Rationale for Use:** Hydroxychloroquine has *in vitro* activity against SARS-CoV-2 and may have immunomodulating properties.\(^{(13)}\) \(^{(14)}\) \(^{(15)}\) \(^{(17)}\)
- **Mechanism of Action:** Mechanisms may include inhibition of viral enzymes or processes such as viral DNA and RNA polymerase, viral protein glycosylation, virus assembly, new virus particle transport, and virus release. Other mechanisms may also involve ACE2 cellular receptor inhibition, acidification at the surface of the cell membrane inhibiting fusion of the virus, and immunomodulation of cytokine release.\(^{(14)}\) \(^{(15)}\) \(^{(29)}\) \(^{(30)}\) \(^{(31)}\) \(^{(32)}\) \(^{(33)}\)
- **FDA Emergency Use Authorization (EUA):** \(^{(66)}\) \(^{(68)}\) \(^{(158)}\)
  - Hydroxychloroquine is not FDA-approved for the treatment of COVID-19.
  - On June 15, 2020, the FDA revoked the EUA for hydroxychloroquine stating that it is unlikely to be effective in treating COVID-19. Also, in light of ongoing serious cardiac adverse events and other serious side effects, the known and potential benefits of hydroxychloroquine no longer outweigh the known and potential risks for the authorized use.
  - The EUA was issued in March 2020 and previously stated that treatment was for adult and adolescent patients weighing 50 kg or more who were hospitalized with COVID-19.
- **Evidence / Experience:**
  - The NIH COVID-19 treatment guidelines recommend against the use of hydroxychloroquine for the treatment of COVID-19 outside of clinical trials. The NIH also recommends against the use of hydroxychloroquine plus azithromycin for the treatment of COVID-19 outside of clinical trials.\(^{(133)}\)
  - Early *in vitro* data and data from small trials are limited and inconclusive.\(^{(12)}\) \(^{(15)}\) \(^{(17)}\) \(^{(18)}\) \(^{(21)}\) \(^{(27)}\) \(^{(69)}\) \(^{(88)}\)
  - In a multicenter, parallel, open-label, randomized trial in 150 adult hospitalized patients, hydroxychloroquine (n = 75) was added to standard therapy.\(^{(127)}\)
    - The majority of patients (n = 148) had mild to moderate disease.
    - The overall 28-day negative viral conversion rate was not different between the two groups (85.4% hydroxychloroquine vs. 81.3% control).
The median time to negative conversion was also similar between groups (8 days hydroxychloroquine vs. 7 days control; HR 0.85; 95% CI, 0.58 to 1.23; p = 0.34).

Negative conversion rates on days 4, 7, 10, 14, and 21 were similar between the groups.

There was no difference in the 28-day symptom alleviation rate (59.9% hydroxychloroquine vs. 66.6% control) and the median time to alleviation of clinical symptoms was similar between the groups (19 days hydroxychloroquine vs. 21 days control; HR 1.01; 95% CI 0.59 to 1.74; p = 0.97).

Adverse events were reported in 9% of the control group and 30% of the hydroxychloroquine group.

Preliminary data from a retrospective analysis (n = 368) assessed the use of either hydroxychloroquine (n = 97) or hydroxychloroquine plus azithromycin (n = 133) in addition to standard of care compared to standard of care alone (n = 158). The cohort consisted of only men in the Veterans Health Administration medical centers with a median age older than 65 years, the majority of whom were black.

The primary outcomes were death and the need for mechanical ventilation.

- Rates of death in the hydroxychloroquine group, the hydroxychloroquine plus azithromycin group, and the standard treatment group were 27.8%, 22.1%, and 11.4%, respectively. Compared to standard therapy, the risk of death from any cause was higher in the hydroxychloroquine group (adjusted HR 2.61; 95% CI, 1.10 to 6.17; p = 0.03), but not in the hydroxychloroquine plus azithromycin group (adjusted HR 1.14; 95% CI, 0.56 to 2.32; p = 0.72).

- Rates of ventilation in the hydroxychloroquine group, the hydroxychloroquine plus azithromycin group, and the standard treatment group were 13.3%, 6.9%, and 14.1%, respectively. Compared to standard therapy, the risk of ventilation was similar in both the hydroxychloroquine group (adjusted HR 1.43; 95% CI, 0.53 to 3.79; p = 0.48) and the hydroxychloroquine plus azithromycin group (adjusted HR 0.43; 95% CI, 0.16 to 1.12; p = 0.09).

An observational trial (n = 1,376) examined the association between hydroxychloroquine use and intubation or death at a large medical center.

- Hydroxychloroquine was not associated with a significantly higher or lower risk of intubation or death (HR 1.04; 95% CI, 0.82 to 1.32); similar results were noted when adjusted for propensity score.

- Hydroxychloroquine-treated patients were more severely ill at baseline.

- Due to wide confidence intervals and the observational nature of the trial, the authors stated that the results should not be utilized to rule out either benefit or harm of hydroxychloroquine and suggested further randomized clinical trials to test efficacy.

An observational study of 1,438 hospitalized patients assessed mortality in patients receiving hydroxychloroquine (n = 271), azithromycin (n = 211), or both (n = 735) compared to patients who received neither of these agents (n = 221).
- There was no difference in mortality in patients treated with hydroxychloroquine (HR 1.08; 95% CI, 0.63 to 1.85), azithromycin (HR 0.56; 95% CI, 0.26 to 1.21), or both (HR 1.35; 95% CI, 0.76 to 2.4) compared with no use of these agents.
- In logistic models, cardiac arrest was significantly more likely in patients receiving hydroxychloroquine plus azithromycin (OR 2.13; 95% CI, 1.12 to 4.05) compared to patients receiving neither drug; however, this was not the case in patients receiving either drug alone.
- In adjusted logistic regression models, there were no significant differences in the relative likelihood of abnormal electrocardiogram findings.
- Patient receiving hydroxychloroquine with or without azithromycin were overall sicker on presentation.

- Data from a randomized, double-blind, placebo-controlled trial in the United States and Canada tested hydroxychloroquine as postexposure prophylaxis for COVID-19 in asymptomatic adults (n = 821) who had household or occupational exposure to someone with confirmed COVID-19 at a distance of less than 6 feet for more than 10 minutes without using a face mask or eye shield (high-risk; n = 719) or while wearing a face mask with no eye shield (moderate risk).(156)
  - Within 4 days of exposure, patients received either placebo or hydroxychloroquine for 5 days.
  - The primary outcome was either a confirmed positive molecular assay or the presence of COVID-19-related symptoms within 14 days.
  - The incidence of new illness compatible with COVID-19 did not significantly differ between patients receiving hydroxychloroquine (49 of 414; 11.8%) and placebo (58 of 407; 14.3%). The absolute difference was -2.4% (95% CI -7 to 2.2; p = 0.35).
  - Side effects were more common with hydroxychloroquine (40.1%) compared to placebo (16.8%).

- A randomized, multicenter, double-blind, placebo-controlled trial (n = 423) studied symptomatic, nonhospitalized adults with laboratory-confirmed COVID-19 or probably COVID-19 and high-risk exposure; patients received either hydroxychloroquine (n = 201) or masked placebo for 5 days.(176)
  - Change in symptom severity over 14 days did not differ between the groups (difference in symptom severity: relative, 12%; absolute, - 0.27 points [95% CI, -0.61 to 0.07 points]; p = 0.117) based on self-assessment.
  - At 14 days, 24% of hydroxychloroquine-treated patients had ongoing symptoms compared with 30% of patients that received placebo (n = 194) (p = 0.21).
  - Medication-related adverse events were reported in 43% of hydroxychloroquine-treated patients compared with 22% of patients that received placebo (p less than 0.001).
  - Ten patients were hospitalized in the placebo group (1 hospitalized death) compared to 4 patients hospitalized in the hydroxychloroquine-treated group (1 nonhospitalized death) (p = 0.29).

- A multicenter, open-label, randomized controlled trial (n = 270) studied nonhospitalized adult patients with recently confirmed SARS-CoV-2 infection with less than 4 days of symptoms; patients received either hydroxychloroquine for 7 days or no antiviral treatment (non-placebo controlled).(177)
No significant differences were found in the mean reduction of viral load at day 3 or day 7.

There was no reduction in the risk of hospitalization (7.1% control vs. 4.9% hydroxychloroquine; RR 0.75 [0.32:1.77]) nor was the time to complete resolution of symptoms shortened (12 days control vs 10 days hydroxychloroquine; p = 0.38).

No major treatment-related adverse events were reported.

- A multicenter, randomized, open-label, three-group, controlled trial (n = 504) studied adult hospitalized patients with suspected or confirmed COVID-19 who were not on supplemental oxygen or were receiving a maximum of 4 L/minute of supplemental oxygen. Patients received either standard care, standard care plus hydroxychloroquine for 7 days, or standard care plus hydroxychloroquine and azithromycin for 7 days.(182)
  - As compared to standard care, the proportional odds of having a higher (worse) score on the seven-point ordinal scale to assess clinical status at 15 days was not affected by either hydroxychloroquine alone (OR 1.21; 95% CI, 0.69 to 2.11; p = 1) or hydroxychloroquine plus azithromycin (OR 0.99; 95% CI, 0.57 to 1.73; p = 1).
  - QT prolongation was more common in the hydroxychloroquine plus azithromycin (14.7%) and the hydroxychloroquine alone (14.6%) groups compared to those receiving only standard care (1.7%); however, fewer patients in the control group had serial electrocardiographic studies performed during follow-up. Doses of hydroxychloroquine were higher than those recommended in the FDA Emergency Use Authorization (EUA).
  - Elevation in hepatic enzymes was more common in patients receiving hydroxychloroquine plus azithromycin (10.9%) and hydroxychloroquine alone (8.5%) than in the control group (3.4%).

- Some protocols have recommendations for use.(12) (21)
- Additional data regarding clinical efficacy for COVID-19 are being evaluated.(16) (31)

**Safety Concerns:** (47) (49)
- Use in COVID-19 patients outside of clinical trials or in a nonhospital setting is not recommended due to the potential for serious adverse events and drug interactions.(141)
- Risk of cardiac arrhythmias (e.g., QT prolongation)
  - Seriously ill patients with comorbidities have an increased risk of serious arrhythmias.(125)
  - Avoid other QT prolonging agents whenever feasible.(125)
- Risk of retinal damage, especially with long term use
- Caution in patients with G6PD deficiency
- Caution in diabetics
- Significant drug interactions
Lopinavir; Ritonavir:

- **Classification:** HIV Protease Inhibitor
- **Rationale for Use:** *In vitro* and animal model studies show potential activity for other coronaviruses (SARS-CoV and MERS-CoV).(4) (52) (53) (54)
- **Mechanism of Action:** Lopinavir and ritonavir may bind to M<sup>pro</sup>, a key enzyme for coronavirus replication. This may suppress coronavirus activity.(55)
- **Evidence / Experience:**
  - Due to unfavorable pharmacodynamics and negative clinical trial data, the NIH COVID-19 treatment guidelines recommend against the use of lopinavir; ritonavir or other HIV protease inhibitors outside of clinical trials.(133) Similarly, ESICM and SCCM Surviving Sepsis Campaign recommendations suggest against the routine use of lopinavir; ritonavir in critically ill adults with COVID-19.(26)
  - Pre-clinical data show activity for other coronaviruses.(4) (52) (53) (54)
  - A randomized controlled trial [i.e., Randomised Evaluation of COVid-19 thERapY (RECOVERY)] compared efficacy of lopinavir; ritonavir (n = 1,596) against usual care alone (n = 3,376) in hospitalized patients with COVID-19.(163)
    - Preliminary data found the 28-day mortality in patients treated with lopinavir; ritonavir was not significantly different from patients who received usual care alone (22.1% vs. 21.3%; RR 1.04; 95% CI, 0.91 to 1.18; p = 0.58).
  - A randomized, controlled, open-label trial involving hospitalized patients with confirmed SARS-CoV-2 infection (n = 199), analyzed treatment with lopinavir; ritonavir.(23)
    - Not associated with a difference from standard of care in the time to clinical improvement (median, 16 days vs. 16 days; hazard ratio 1.31; 95% CI, 0.95 to 1.80; p = 0.09); percentages of patients with detectable viral RNA were similar; 28 day mortality was also similar (19.2% vs. 25%, respectively).
  - A retrospective cohort study of hospitalized patients reviewing clinical course and risk factors for mortality included 29 patients who received lopinavir; ritonavir.(24)
    - No difference was noted in the duration of viral shedding after treatment with lopinavir; ritonavir.
- **Safety Concerns:** (45) (49) (125) (172)
  - Risk of cardiac arrhythmias (e.g., QT prolongation)
    - Seriously ill patients with comorbidities have an increased risk of serious arrhythmias.
    - Avoid other QT prolonging agents whenever feasible.
  - Bradycardia
  - Caution in patients with hepatic disease or hepatitis
  - Significant drug interactions
Favipiravir:

- **Classification:** Investigational RNA-Dependent RNA Polymerase Inhibitor
- **Rationale for Use:** Favipiravir is a broad-spectrum antiviral with *in vitro* activity against RNA viruses. (14) (18) (75)
- **Mechanism of Action:** Favipiravir is an RNA-dependent RNA polymerase (RdRp) inhibitor that inhibits viral RNA synthesis. (14) (18) (75)
- **Evidence / Experience:**
  - In a non-randomized, controlled, open-label trial, the efficacy of favipiravir (n = 35) in treating patients with laboratory confirmed COVID-19 was compared against lopinavir; ritonavir (n = 45); both treatments were given in combination with inhaled interferon alpha. (142)
    - Time to viral clearance was shorter for favipiravir (median, 4 days; range, 2.5 to 9 days) than for lopinavir; ritonavir (median, 11 days; range 8 to 13 days; *p* less than 0.001).
    - Chest imaging improvement rate at treatment day 14 was 91% for favipiravir vs. 62% for lopinavir; ritonavir (*p* = 0.004)
  - A prospective, randomized, controlled, open-label multicenter trial compared favipiravir (n = 116) against umifenovir [Arbidol] (n = 120) in treating patients with COVID-19; both treatments were given in combination with conventional therapy. (143)
    - No difference in clinical recovery rate at treatment Day 7 (61% for favipiravir vs. 52% for umifenovir; *p* = 0.1396; 95% CI: -0.0305 to 0.2213).
  - A multicenter, randomized, Phase II/III trial comparing efficacy of favipiravir to standard care in 60 adults hospitalized with moderate COVID-19 pneumonia. (189)
    - On day 5, viral clearance was achieved in 62.5% of patients on favipiravir (n = 25/40) and 30% of patients on standard care (n = 6/20), *p* = 0.018.
    - On day 10, viral clearance was achieved in 92.5% of patients on favipiravir (n = 37/40) and 80% of patients on standard care (n = 16/20), *p* = 0.155.
    - Standard care patients (n = 20) were allowed to use other antivirals or antimalarials, however, those receiving favipiravir were not; of the standard care patients, 15 received hydroxychloroquine/chloroquine, 1 received lopinavir; ritonavir, and 4 received no additional antiviral or antimalarial treatment.
    - 17.5% (n = 7/40) of favipiravir recipients experienced adverse events, including diarrhea, nausea, chest pain, and increased hepatic enzymes.
  - Additional data regarding clinical efficacy for COVID-19 are being evaluated. (132)
- **Safety Concerns:**
  - Contraindicated in pregnancy due to early embryonic death and teratogenicity observed in animal studies.

---

**Adjunctive/Supportive therapy:**

**Anticoagulation:**

Updated August 12, 2020
Copyright © 2020 Elsevier
Venous thromboembolism (VTE) prophylaxis with LMWH is recommended for all hospitalized patients with COVID-19 infection. Withhold VTE prophylaxis for active bleeding, platelet count less than 25 x 10^9/L, or fibrinogen less than 0.5 g/L.\(^{(80)}\) \(^{(81)}\) \(^{(91)}\) \(^{(95)}\) \(^{(102)}\) \(^{(160)}\)

- In acutely ill hospitalized COVID-19 patients, anticoagulant prophylaxis with LMWH or fondaparinux is recommended over unfractionated heparin (UFH); LMWH, fondaparinux, or UFH is recommended over a direct oral anticoagulant (DOAC).\(^{(160)}\)
- In critically ill COVID-19 patients, anticoagulant prophylaxis with LMWH is recommended over UFH; LMWH or UFH is recommended over fondaparinux or DOAC.\(^{(160)}\)
- Use fondaparinux in patients with a history of heparin-induced thrombocytopenia.\(^{(95)}\)
- Use UFH or reduced-dose LMWH in patients with creatinine clearance less than 30 mL/minute.\(^{(103)}\)
- Use mechanical thromboprophylaxis in patients where anticoagulants are contraindicated or unavailable.\(^{(95)}\) \(^{(160)}\)
- Standard dose anticoagulant thromboprophylaxis is recommended over intermediate (LMWH twice daily or increased weight-based dosing) or full treatment dosing.\(^{(160)}\)
  - Data are insufficient to recommend the use of increasing anticoagulant doses for VTE prophylaxis in hospitalized COVID-19 patients outside of a clinical trial.\(^{(95)}\) \(^{(133)}\)
- Hospitalized patients with COVID-19 should not routinely be discharged on VTE prophylaxis. Weighing the individual patient’s VTE risk factors and bleeding risk in addition to feasibility, may consider extended thromboprophylaxis after discharge.\(^{(95)}\) \(^{(133)}\) \(^{(160)}\)
  - Aspirin could be considered for COVID-19 VTE prophylaxis if criteria for post-discharge thromboprophylaxis are met.\(^{(95)}\)
- Elevated D-dimer has been noted in COVID-19 patients requiring hospitalization and has been associated with increased mortality. Limited data suggest a decrease in mortality in patients with severe COVID-19 infection or markedly elevated D-dimer concentrations (more than 6 times the upper limit of normal) who were given LMWH or heparin VTE prophylaxis.\(^{(80)}\) \(^{(81)}\) \(^{(91)}\) \(^{(102)}\)

- Therapeutic-intensity anticoagulation is not recommended in the management of COVID-19 in the absence of confirmed or suspected VTE outside of a clinical trial.\(^{(95)}\) \(^{(128)}\)
  - In patients already anticoagulated for VTE or atrial fibrillation, continue therapeutic anticoagulation. Consider withholding therapeutic anticoagulation in these patients for platelet count less than 30-50 x 10^9/L or fibrinogen less than 1 g/L.\(^{(102)}\)
  - In outpatient COVID-19 patients with proximal deep vein thrombosis (DVT) or pulmonary embolism (PE) and no drug-drug interactions, apixaban, dabigatran, rivaroxaban, or edoxaban are recommended; initial parenteral anticoagulation is necessary for dabigatran and edoxaban.\(^{(160)}\)
    - If DOAC is not used, warfarin (overlapped with parenteral anticoagulation) is recommended over LMWH for patient convenience.\(^{(160)}\)
  - In acutely ill hospitalized COVID-19 patients with proximal DVT or PE, therapeutic LMWH or UFH is favored over oral anticoagulation; LMWH use will limit staff exposure.
    - In the absence of drug-drug interactions, initial oral anticoagulation with apixaban or rivaroxaban is recommended; dabigatran or edoxaban can be used after initial parenteral anticoagulation, and warfarin may be used after overlap with parenteral anticoagulation.\(^{(160)}\)
In critically ill COVID-19 patients with proximal DVT or PE, parenteral anticoagulant therapy is recommended over oral anticoagulation; LMWH or fondaparinux is recommended over UFH.(160)

In COVID-19 patients with recurrent VTE despite anticoagulation with therapeutic LMWH (and documented compliance), increase the LMWH dose by 25% to 30%. If recurrent VTE occurs in a patient compliant with DOAC or therapeutic warfarin, switch treatment to therapeutic LMWH.(160)

Treat all COVID-19 patients with confirmed or suspected VTE with therapeutic anticoagulation for at least 3 months. Therapeutic anticoagulation may be discontinued at 3 months if the patient has recovered from COVID-19 and has no ongoing risk factors for thrombosis or other indications for anticoagulation.(128) (160)

Increasing the intensity of anticoagulation (i.e., from standard-intensity prophylaxis to intermediate-intensity prophylaxis or from intermediate-intensity prophylaxis to therapeutic-intensity prophylaxis) may be reasonable in COVID-19 patients who experience recurrent clotting of access devices or extracorporeal circuits.(95)

Azithromycin:

- **Classification:** Macrolide Antibacterial
- **Rationale for Use:** Azithromycin may prevent bacterial superinfection, and macrolides may have immunomodulatory properties to work as adjunct therapy.(27) (34) (35) (36) (37)
- **Mechanism of Action:** Macrolides may have immunomodulatory properties in pulmonary inflammatory disorders. They may downregulate inflammatory responses and reduce the excessive cytokine production associated with respiratory viral infections; however, their direct effects on viral clearance are uncertain. Immunomodulatory mechanisms may include reducing chemotaxis of neutrophils (PMNs) to the lungs by inhibiting cytokines (i.e., IL-8), inhibition of mucus hypersecretion, decreased production of reactive oxygen species, accelerating neutrophil apoptosis, and blocking the activation of nuclear transcription factors.(34) (35) (36) (37)
- **Evidence / Experience:**
  - Due to the potential for toxicities, the NIH COVID-19 treatment guidelines recommend against the use of azithromycin in combination with hydroxychloroquine outside of clinical trials.(133)
  - Early data from small trials and trials outside of COVID-19 are limited and inconclusive.(27) (28) (88)
  - An observational study of 1,438 hospitalized patients assessed mortality in patients receiving hydroxychloroquine (n = 271), azithromycin (n = 211), or both (n = 735) compared to patients who received neither of these agents (n = 221).(151)
    - There was no difference in mortality in patients treated with hydroxychloroquine (HR 1.08; 95% CI, 0.63 to 1.85), azithromycin (HR 0.56; 95% CI, 0.26 to 1.21), or both (HR 1.35; 95% CI, 0.76 to 2.4) compared with those not receiving these agents.
    - In logistic models, cardiac arrest was significantly more likely in patients receiving hydroxychloroquine plus azithromycin (OR 2.13; 95% CI, 1.12 to 4.05) compared to patients receiving neither drug; however, this was not the case in patients receiving either drug alone.
In adjusted logistic regression models, there were no significant differences in the relative likelihood of abnormal electrocardiogram findings.

- A multicenter, randomized, open-label, three-group, controlled trial (n = 504) studied adult hospitalized patients with suspected or confirmed COVID-19 who were not on supplemental oxygen or were receiving a maximum of 4 L/minute of supplemental oxygen. Patients received either standard care, standard care plus hydroxychloroquine for 7 days, or standard care plus hydroxychloroquine and azithromycin for 7 days. (182)
  - As compared to standard care, the proportional odds of having a higher (worse) score on the seven-point ordinal scale to assess clinical status at 15 days was not affected by hydroxychloroquine plus azithromycin (OR 0.99; 95% CI, 0.57 to 1.73; p = 1).
  - QT prolongation was more common in the hydroxychloroquine plus azithromycin (14.7%) group compared to those receiving only standard care (1.7%); however, fewer patients in the control group had serial electrocardiographic studies performed during follow-up.
  - Elevation in hepatic enzymes was more common in patients receiving hydroxychloroquine plus azithromycin (10.9%) than in the control group (3.4%).

- **Safety Concerns**: (48) (49)
  - Risk of cardiac arrhythmias (e.g., QT prolongation)
    - Seriously ill patients with comorbidities have an increased risk of serious arrhythmias. (125)
    - Avoid other QT prolonging agents whenever feasible. (125)
  - Significant drug interactions

**Bronchodilators:**

- Most patients with COVID-19 do not need inhaled bronchodilator therapy. There is no role for inhaled bronchodilators in the management of COVID-19 unless the patient has underlying asthma or chronic obstructive pulmonary disease (COPD). (57) (61)
  - MDIs are preferred due to the potential for generation of aerosols that may increase the risk of viral transmission with nebulized therapy. (57) (61)
  - Due to concerns about supply chain interruption, some institutions are developing an MDI canister reassignment protocol to address potential shortages. An MDI canister reassignment protocol should emphasize hand hygiene and dual canister disinfection and avoid inadvertent sources of transmission. (57) (79)

**Bruton’s Tyrosine Kinase (BTK) Inhibitors:**

- **Rationale for Use:** Cytokine release syndrome may be a component of severe disease in COVID-19 patients. (24) (89) (90) (178)
- **Mechanism of Action:** Bruton’s tyrosine kinases are macrophage signaling molecule. When stimulated by viruses such as SAR-CoV-2, BTK activates NF-kB, resulting in production of inflammatory cytokines and chemokines as well as phagocytosis. BTK also activates NLRP3 inflammasome, resulting in maturation and secretion of IL-1 beta. BTK inhibitors form a
covalent bond with a cysteine residue in the BTK active site, leading to inhibition of BTK enzymatic activity. (178) (179) (180) (181)

- **Evidence / Experience:**
  - Due to the broad immunosuppressive effect, the NIH COVID-19 treatment guidelines recommend against the use of BTK inhibitors outside of clinical trials. (133)

- **Safety Concerns:** (179) (180) (181)
  - Caution in patients with neutropenia, thrombocytopenia, and anemia
  - Bleeding risk (intracranial bleeding, GI bleeding, hematuria, hemothorax)
  - Monitor for elevated liver function tests (LFTs)
  - Cardiac arrhythmias (atrial fibrillation, atrial flutter, ventricular arrhythmias)
  - Avoid use during pregnancy

**Colchicine:**

- **Classification:** Anti-inflammatory Agent
- **Rationale for Use:** Cytokine release syndrome may be a component of severe disease in COVID-19 patients. (24) (89) (90) (107)
- **Mechanism of Action:** Colchicine downregulates multiple pro-inflammatory pathways and increases levels of anti-inflammatory mediators. It also prevents microtubule assembly and thereby disrupts inflammasome activation, microtubule-based inflammatory cell chemotaxis, phagocytosis, and generation of leukotrienes and cytokines (including interleukin-1 beta). Consequently, colchicine prevents the activation, degranulation, and migration of neutrophils. (165) (166) (167)
- **Evidence / Experience:**
  - A prospective, open-label, multicenter, randomized trial compared the efficacy of colchicine plus standard care (n = 55) against standard care alone (n = 50) in hospitalized patients with COVID-19. (164)
    - The primary clinical end point was time to clinical deterioration by 2 points on a 7-grade clinical status scale which ranged from resumption of normal activities to death. This clinical end point occurred in 1 patient in the colchicine group and in 7 patients who received standard care alone (1.8% vs. 14%; OR 0.11; 95% CI, 0.01 to 0.96; p = 0.046). Compared to the colchicine group, the rate of clinical deterioration was higher and the time to clinical deterioration was shorter in the standard care group. The patient in the colchicine group who met the end point needed mechanical ventilation and subsequently died. Of the 7 standard care patients meeting the clinical endpoint, 1 required noninvasive mechanical ventilation, 5 were intubated and mechanically ventilated (3 died shortly after intubation), and 1 died suddenly of cardiorespiratory arrest in the ward.
    - The mean event-free survival time for colchicine was 20.7 days in the colchicine group and 18.6 days in the standard care alone group (p = 0.03).
    - Standard care treatments included chloroquine, hydroxychloroquine, azithromycin, lopinavir; ritonavir, and tocilizumab. Remdesivir was not used in any patient.
A single-center cohort comparing the efficacy of colchicine plus standard care (n = 122) against standard care alone (n = 140) in hospitalized adults with COVID-19 pneumonia and acute respiratory distress syndrome.(186)

- Survival at day 21 was achieved by 84.2% of patients in the colchicine group and 63.6% of patients in the control group (p = 0.001).
- The Cox proportional hazards regression survival analysis suggest colchicine is independently associated with a lower risk of death (HR = 0.151; 95% CI, 0.062 to 0.368; p less than 0.0001).
- Standard care treatments included hydroxychloroquine, intravenous dexamethasone, and lopinavir; ritonavir.
  - A significantly higher percentage of patients in the colchicine group received concurrent treatment with dexamethasone.
  - Significantly more patients in the control group received treatment with lopinavir; ritonavir.

Safety Concerns: (165) (166)

- Gastrointestinal reactions (abdominal pain, diarrhea, nausea, and vomiting)
- Neuromuscular toxicity and rhabdomyolysis
- Caution in patients with bone marrow suppression
- Caution in patients with renal or hepatic impairment

Corticosteroids:

- Guidelines from the NIH and IDSA recommend the use of dexamethasone (for up to 10 days) in patients with COVID-19 who are mechanically ventilated and patients with COVID-19 who require supplemental oxygen but are not mechanically ventilated. The guidelines recommend against using dexamethasone in patients with COVID-19 who do not require supplemental oxygen.(133) (161)
  - Clinicians are advised to review the patient's medical history and assess the potential risks and benefits before initiating dexamethasone.
  - If dexamethasone is not available, it is recommended to use an alternative corticosteroid such as prednisone, methylprednisolone, or hydrocortisone; however, it is unclear if these alternatives will provide the same benefit as dexamethasone.
  - Oral and inhaled corticosteroids that were used prior to COVID-19 diagnosis for another underlying condition should not be discontinued.

- Evidence / Experience:
  - Preliminary data from a randomized controlled trial (i.e., RECOVERY trial) of hospitalized patients with COVID-19 found dexamethasone reduced deaths in patients with severe respiratory complications.(159)
    - Overall mortality at 28 days was significantly lower in the dexamethasone group (22.9%; n = 482 of 2,104) than in the usual care group (25.7%; n = 1,110 of 4,321) (rate ratio 0.83; 95% CI, 0.75 to 0.93; p less than 0.001).
    - In patients receiving mechanical ventilation, the incidences of death for dexamethasone and the usual care group were 29.3% and 41.4%, respectively (rate ratio 0.64; 95% CI, 0.51 to 0.81).
In patients receiving oxygen without mechanical ventilation, the incidences of death for dexamethasone and the usual care group were 23.3% and 26.2%, respectively (rate ratio, 0.82; 95% CI, 0.72 to 0.94).

No benefit was observed in patients not requiring respiratory support (17.8% vs. 14%; rate ratio 1.19; 95% CI, 0.91 to 1.55).

- Data from a single-center, retrospective cohort showed higher survival rates in hospitalized patients with COVID-19 pneumonia who received treatment with a glucocorticoid. (162)
  - The in-hospital mortality was lower in patients treated with steroids (n = 396) than in patients who were not (n = 67) (13.9% vs. 23.9%; HR 0.51; [0.27 to 0.96]; p = 0.044); overall mortality was reduced by 41.8% relative to no steroid treatment (RRR 0.42 [0.048 to 0.65]).
- An observational study of 72 patients diagnosed with SARS-CoV-2 pneumonia who received tocilizumab (in addition to antiviral therapy) evaluated the efficacy of adding methylprednisolone (n = 56) vs. no steroid (n = 16). (170)
  - Overall death occurred in 21 of 72 patients (29.2%), 10 of 16 non-steroid patients (62.5%), 11 of 56 methylprednisolone-treated patients (19.6%).
  - The primary outcome of in-hospital, all-cause mortality was lower in patients receiving methylprednisolone plus tocilizumab (RR 0.2; 95% CI, 0.08 to 0.47; p less than 0.01).
- A study (n = 172) compared patients with COVID-19-associated cytokine storm syndrome (CSS) who received steroids with or without tocilizumab to historical controls. (183)
  - Patients received high-dose IV methylprednisolone for 5 consecutive days (optional 2 day extension). If the respiratory condition had not improved sufficiently, tocilizumab was administered between day 2 and 5 as a single infusion.
  - Of the 86 treated patients, 37 (43%) received tocilizumab. Two patients received a second dose of tocilizumab.
  - Patients in the treatment group had 79% higher likelihood of reaching 2-stage improvement in respiratory status (HR: 1.79; 95% CI, 1.2 to 2.67) and they reached, on average, 7 days (median) earlier than the control group.
  - WHO-endorsed 7-point ordinal scores were better in the treatment group at days 7 and 14 (p less than 0.0001).
  - Hospital mortality was 65% lower in the treatment group compared to the control group (HR: 0.35; 95% CI, 0.19 to 0.65). At hospital day 14, 10 patients had died in the treatment group compared with 33 in the control group (p less than 0.0001).
  - The likelihood to require mechanical ventilation was 71% lower in the treatment group compared to the control group (HR: 0.29; 95% CI, 0.14 to 0.6). Among patients not mechanically ventilated at baseline, the daily incidence of mechanical ventilation (new start) was 1.3% in the treatment group compared to 5.4% in the control group (p = 0.0003).
  - In the sensitivity analysis that excluded patients who received tocilizumab, the treatment effects for all outcomes increased and maintained statistical significance with the steroid alone.
An observational study \((n = 1,806)\) reviewed the effects of early steroid use \((n = 140)\) compared to no steroid use in hospitalized patients with COVID-19.\(^{185}\)

- Patients in the treatment group received steroids within 48 hours of admission.
- Overall, early use of steroids was not associated with in-hospital mortality or mechanical ventilation.
- Early steroid use in patients with an initial C-reactive protein (CRP) of 20 mg/dL or higher was associated with a significantly reduced risk of mortality or mechanical ventilation in unadjusted \((OR, 0.23; 95\% CI, 0.08 \text{ to } 0.7)\) and adjusted \((aOR, 0.2; 95\% CI, 0.06 \text{ to } 0.67)\) analyses.
- Early steroid use in patients with an initial CRP of less than 10 mg/dL was associated with a significantly increased risk of mortality or mechanical ventilation in unadjusted \((OR, 2.64; 95\% CI, 1.39 \text{ to } 5.03)\) and adjusted \((aOR, 3.14; 95\% CI 1.52 \text{ to } 6.5)\) analyses.

- **Safety Concerns:** \(^{133} \) \(^{173} \) \(^{187} \)
  - Hyperglycemia
  - Secondary infections/reactivation of latent infections
  - Psychiatric effects

**COVID-19 Convalescent Plasma:** \(^{22} \)

- **Classification:** Plasma collected from persons who have recovered from COVID-19 that may contain antibodies to SARS-CoV-2
- **Rationale for Use:** Clinical trials are being conducted to evaluate the use of COVID-19 convalescent plasma to treat patients with severe or immediately life-threatening COVID-19 infections. COVID-19 convalescent plasma is not intended for prevention of the infection.
  - To participate in these trials, investigators should submit requests to the FDA for investigational use under the traditional IND regulatory pathway.
  - In addition to clinical trials, licensed physicians may obtain COVID-19 convalescent plasma for an individual patient through the process of single patient eINDs.
- **Evidence / Experience:**
  - Due to a lack of clinical data, the NIH COVID-19 treatment guidelines do not give recommendations for or against the use of convalescent plasma.\(^{133} \)
  - A randomized, open-label, multicenter trial evaluating efficacy and safety of convalescent plasma in hospitalized patients with severe or life-threatening COVID-19.\(^{157} \)
    - No significant difference in time to clinical improvement within 28 days between convalescent plasma plus standard treatment \((51.9\%, n = 27/52)\) and standard treatment alone \((43.1\%, n = 22/51)\) \((\text{difference, 8.8\% [95\% CI, -10.4\% to 28\%]; HR 1.40 [95\% CI, 0.79 to 2.49]; p = 0.26).}\)
    - No significant difference in 28-day mortality \((15.7\% \text{ vs. } 24\%; OR, 0.59; 95\% CI, 0.22 \text{ to } 1.59; p = 0.3).\)
    - Two convalescent plasma recipients experienced transfusion-related adverse events.
  - In a case series of 5 critically ill patients with confirmed COVID-19 and ARDS, patients received convalescent plasma.\(^{65} \)
Treatment: 2 consecutive transfusions of 200 mL to 250 mL of convalescent plasma (total dose: 400 mL) with a SARS-CoV-2-specific antibody (IgG) titer greater than 1:1,000 on the same day it was obtained from the donor.

Patient criteria included:
- Severe pneumonia with rapid progression and continuously high viral load despite antiviral treatment
- PAO₂/FIO₂ less than 300
- Mechanical ventilation

After plasma infusion, body temperature normalized within 3 days in 4 of 5 patients, Sequential Organ Failure Assess (SOFA) score decreased and PAO₂/FIO₂ increased within 12 days.

Viral loads decreased and became negative within 12 days after the transfusion with the SARS-CoV-2-specific ELISA and neutralizing antibody titers increased after the transfusion.

ARDS resolved in 4 patients by day 12 after the transfusion and 3 patients were weaned from mechanical ventilation within 2 weeks of treatment.

In a case series of 6 critically ill patients with confirmed COVID-19 with abnormalities on chest CT (with the exception of 1 patient) who were deteriorating while receiving standard treatment, patients received convalescent plasma.

Patients received at least 1 cycle (range, 1 to 3 cycles) of convalescent plasma (200 mL per cycle) over 30 minutes.

All patients had improved symptoms and chest CT and were discharged from the hospital.

Safety Concerns:
- Safety data from 5,000 hospitalized adults with severe or life-threatening COVID-19 who received convalescent plasma (range: 200 to 500 mL).
  - 36 serious adverse events (SAEs) within 4 hours of transfusion (less than 1% of all transfusions)
    - 15 deaths (0.3% of all transfusions); 4 were attributed to treatment (possibly n = 3; probably n = 1; definitely n = 0)
    - 21 non-lethal SAEs
      - 7 transfusion-associated circulatory overload (TACO) and 11 transfusion-related acute lung injury (TRALI); all were attributed to treatment (possibly n = 9; probably n = 7; definitely n = 2)
      - 3 severe allergic transfusion reactions
  - Seven-day mortality rate was 14.9%

- Safety data from the first consecutive 20,000 adults to receive COVID-19 convalescent plasma (range: 200 to 500 mL) through a national expanded access program.
  - 146 SAEs within 4 hours of transfusion (less than 1% of all transfusions)
    - 63 deaths; 13 were deemed possibly or probably related to treatment
    - 83 non-lethal SAEs
      - 37 TACO and 20 TRALI
      - 26 severe allergic transfusion reactions
  - Life-threatening cardiac and thrombotic events within 7 days of transfusion included 643 cardiac events, 406 sustained hypotension, 87 thrombotic or thromboembolic complications
  - Seven-day mortality rate was 8.6%
Fibrinolytics:

- **Rationale for Use:** Severe COVID-19 infection is associated with coagulopathy, specifically a prothrombotic disseminated intravascular coagulation (DIC) with high rates of VTE, vascular occlusive events, and central line thrombosis and pulmonary congestion with microvascular thrombosis and occlusion observed on pathology. Fibrin deposition in the pulmonary microvasculature is a causative factor in the development of ARDS. (102) (136)
- **Mechanism of Action:** Fibrinolytic agents act by converting plasminogen to plasmin on the surface of existing thrombi, thereby initiating local fibrinolysis. (137)
- **Evidence / Experience:**
  - **Alteplase:**
    - In a case series of 3 critically ill patients with ARDS and respiratory failure, patients received alteplase followed by intravenous heparin. (136)
    - \(\text{PaO}_2/\text{FiO}_2\) (P/F) ratio improved by 11% to 100% in all 3 patients; however, the improvements were transient.
    - Additional data regarding clinical efficacy for COVID-19 are being evaluated. (138)
  - **Other fibrinolytics for which COVID-19 efficacy data are being evaluated include defibrotide.** (139) (140)
- **Safety Concerns:** (136) (137)
  - **Bleeding**
  - In COVID-19 patients with acute, objectively confirmed PE and hypotension or signs of obstructive shock who are not at high risk of bleeding, systemically administered thrombolytics are recommended. Thrombolytic therapy is also recommended for COVID-19 patients with acute PE experiencing cardiopulmonary deterioration due to PE after initiation of anticoagulant therapy who have not yet developed hypotension and who are at low risk for bleeding. (160)
    - Systemic thrombolysis using a peripheral vein is recommended over catheter-directed thrombolysis. (160)

Inhaled Pulmonary Vasodilators:

- There is no evidence for routine use of inhaled pulmonary vasodilators (e.g., nitric oxide, prostacyclins) in acute respiratory failure in COVID-19 patients. Avoid aerosolized vasodilators. (26) (60) (61) (133)
- Use may be considered in specific patients with ARDS as a temporizing measure when patients develop refractory hypoxemia despite optimization of ventilation and other rescue strategies. (26) (60)
- If inhaled pulmonary vasodilator therapy is used, a short trial with preestablished criteria for ongoing use or discontinuation is recommended. (26) (61) (133)
- Additional data regarding clinical efficacy for COVID-19 are being evaluated. (58) (59)

Interleukin-1 (IL-1) Antagonists:
• **Rationale for Use:** Cytokine release syndrome may be a component of severe disease in COVID-19 patients. (24) (89) (90) (107)

• **Mechanism of Action:** Interleukin-1 antagonists, such as anakinra and canakinumab, prevent the binding of IL-1 (a pro-inflammatory cytokine that mediates various inflammatory and immunological responses, including activation of IL-6) to interleukin-1 receptors. Anakinra acts similarly to the native interleukin-1 receptor antagonist by competitively inhibiting the binding of both IL-1 alpha and IL-1 beta to the IL-1 type 1 receptor. Canakinumab is a human monoclonal antibody that specifically targets and neutralizes IL-1 beta; thereby preventing its interaction with IL-1 receptors. (89) (106) (147)

• **Evidence / Experience:**
  
  - Due to a lack of clinical data, the NIH COVID-19 treatment guidelines do not give recommendations for or against the use of IL-1 antagonists. (133)
  
  - **Anakinra:**
    
    § Retrospective cohort study comparing anakinra plus standard therapy to standard therapy alone in patients with COVID-19, moderate-to-severe ARDS, and hyperinflammation. (148)
    
    * 21-day survival was 90% in the anakinra group and 56% in standard treatment group (p = 0.009). Respiratory function improved in 72% (n = 21/29) of anakinra patients and 50% (n = 8/16) of patients in the standard treatment group.
    
    § Single-center study comparing anakinra plus standard therapy (n = 52) to a historical control group of standard therapy plus supportive care (n = 44) in adults with severe COVID-19-related bilateral pneumonia. (174)
    
    * The primary outcome of admission to intensive care for mechanical ventilation or death occurred in 25% of patients receiving anakinra and 73% of patients in the control group (HR 0.22; 95% CI, 0.11 to 0.41; p less than 0.001).

  - Additional data regarding clinical efficacy for COVID-19 are being evaluated. (132)

    - Other IL-1 antagonists for which COVID-19 efficacy data are being evaluated include canakinumab. (132)

• **Safety Concerns:** (106) (147)

  - Caution in patients with thrombocytopenia and neutropenia
  
  - Infusion-related reactions (anakinra)

---

**Interleukin-6 (IL-6) Receptor Antagonists:**

• **Rationale for Use:** Cytokine release syndrome may be a component of severe disease in COVID-19 patients. (24) (25) (89) (90)

• **Mechanism of Action:** IL-6 receptor-inhibiting monoclonal antibodies block IL-6-mediated signaling by competitively binding to both soluble and membrane-bound IL-6 receptors (sIL-6R and mIL-6R). IL-6 is a proinflammatory cytokine that is involved in diverse physiological processes such as T-cell activation, immunoglobulin secretion induction, hepatic acute-phase protein synthesis initiation, and hematopoietic precursor cell proliferation and differentiation stimulation. IL-6 is produced by various cell types, including T- and B-cells, lymphocytes, monocytes, and fibroblasts. (52) (72) (78) (97) (98)
Evidence / Experience:

- Due to a lack of clinical data, the NIH COVID-19 treatment guidelines do not recommend for or against the use of IL-6 receptor inhibitors.(133)
  - Siltuximab:
    - A retrospective study of 21 patients with COVID-19 induced pneumonia/ARDS analyzed patients who received treatment with siltuximab.(101)
      - CRP concentrations reduced to within normal range by day 5 and remained stable in all 16 patients with available data; 33% (n = 7/21) condition improved with reduced need for ventilation; 43% (n = 9/21) condition stabilized; 24% (n = 5/21) condition worsened and required intubation.
      - A cohort study of patients treated with standard therapy is ongoing
    - Additional data regarding clinical efficacy for COVID-19 are being evaluated.(132)
  - Tocilizumab:
    - A single-center, observational study of mechanically ventilated patients with COVID-19 comparing tocilizumab treatment (n = 78) with tocilizumab-untreated controls (n = 76).(171)
      - Tocilizumab was associated with a reduction in the hazard of death (adjusted HR 0.54; 95% CI, 0.29 to 1), and a lower 28-day case fatality rate (18% vs. 36%; p= 0.01).
      - Tocilizumab was associated with an increased risk for superinfections (overall, 54% vs. 26%; p less than 0.001; ventilator-associated pneumonia, 45% vs. 20%; p less than 0.001); however, there was no difference in the 28-day case fatality rate in tocilizumab recipients with vs. without superinfection (22% vs. 15%; p = 0.42).
    - A single-arm, multicenter, prospective, open-label study to evaluate the efficacy of intravenous and subcutaneous tocilizumab in 63 hospitalized adults with severe COVID-19.(175)
      - The overall mortality rate at day 14 was 11% (n = 7 of 63); no difference in mortality was observed based on route of administration (12.9%, intravenous; 10.3% subcutaneous).
      - Treatment was associated with improvement in levels of ferritin, C-reactive protein, D-dimer, and lymphocytes.
    - A retrospective review analyzed 21 patients in which tocilizumab was added to standard COVID-19 therapy.(25)
      - Preliminary data suggest tocilizumab may have clinical benefit as adjunctive therapy.
      - Clinical symptoms, CT opacity changes, lymphocyte percentage, and CRP concentrations all improved in these patients; however, no comparators were reported.
    - A study (n = 172) compared patients with COVID-19-associated cytokine storm syndrome (CSS) who received steroids with or without tocilizumab to historical controls.(183)
      - Patients received high-dose IV methylprednisolone for 5 consecutive days (optional 2 day extension). If the respiratory condition had not
improved sufficiently, tocilizumab was administered between day 2 and 5 as a single infusion.

- Of the 86 treated patients, 37 (43%) received tocilizumab. Two patients received a second dose of tocilizumab.
- Patients in the treatment group had 79% higher likelihood of reaching 2-stage improvement in respiratory status (HR: 1.79; 95% CI, 1.2 to 2.67) and they reached, on average, 7 days (median) earlier than the control group.
- WHO-endorsed 7-point ordinal scores were better in the treatment group at days 7 and 14 (p less than 0.0001).
- Hospital mortality was 65% lower in the treatment group compared to the control group (HR: 0.35; 95% CI, 0.19 to 0.65). At hospital day 14, 10 patients had died in the treatment group compared with 33 in the control group (p less than 0.0001).
- The likelihood to require mechanical ventilation was 71% lower in the treatment group compared to the control group (HR: 0.29; 95% CI, 0.14 to 0.6). Among patients not mechanically ventilated at baseline, the daily incidence of mechanical ventilation (new start) was 1.3% in the treatment group compared to 5.4% in the control group (p = 0.0003).

- Single-center, retrospective, observational cohort study evaluating efficacy of subcutaneous tocilizumab plus standard care in 12 adults with severe COVID-19-related cytokine release syndrome (CRS).(188)
  - The primary assessment was incidence of grade 4 CRS after administration of tocilizumab
    - Within 2 days of drug administration, 5 of 12 patients (42%) had grade 4 CRS.
    - Within 1 week of drug administration, no cases were observed.
  - No adverse events or new safety concerns were attributed to tocilizumab.
  - Some protocols include recommendations for use.(21)
  - Additional data regarding clinical efficacy for COVID-19 are being evaluated.(132)
    - Other IL-6 receptor inhibitors for which COVID-19 efficacy data are being evaluated include clazakizumab and sarilumab.(132)

- Safety Concerns: (52) (78) (97)
  - Risk of GI perforation
  - Risk of hepatotoxicity
  - Caution in patients with thrombocytopenia and neutropenia
  - Infusion-related reactions

Janus Kinase (JAK) Inhibitors:

- Rationale for Use: Cytokine release syndrome may be a component of severe disease in COVID-19 patients.(24) (89) (90) (94)
- Mechanism of Action: Janus kinases are intracellular enzymes that transmit signals arising from the interaction of cytokines and growth factors with receptors located on the cellular membrane. These enzymes phosphorylate and activate signal transducers and activators of
transcription proteins (STATs), which modulate intracellular activity including gene expression. The JAK-mediated signaling pathway is pivotal in influencing immune system activation, as cytokine receptors are expressed on most immune cells. JAK inhibitors modulate the signaling pathway by preventing the phosphorylation and activation of STATs.(92) (130) (131)

- **Evidence / Experience:**
  - Due to the broad immunosuppressive effect, the NIH COVID-19 treatment guidelines recommend against the use of JAK inhibitors outside of clinical trials.(133)
  - **Baricitinib:**
    - An observational, retrospective, longitudinal, multicenter trial of hospitalized patients with moderate COVID-19 pneumonia was conducted to compared safety and efficacy of baricitinib plus lopinavir; ritonavir (n = 113) against standard of care (n = 78, hydroxychloroquine plus lopinavir; ritonavir).(144)
      - The 2-week case fatality rate was significantly lower in the baricitinib group than in patients treated with standard of care (0% vs. 6.4%; 95% CI, 0 to 0.4569; p = 0.01).
      - In the baricitinib group, 7 adverse events were reported. None required treatment discontinuation.
      - The median time to initiation of baricitinib therapy was 7 days from symptom onset.
    - Additional data regarding clinical efficacy for COVID-19 are being evaluated.(132)
  - **Ruxolitinib**
    - A randomized, multicenter, placebo-controlled, Phase 2 trial evaluated the efficacy and safety of ruxolitinib in hospitalized patients with severe COVID-19.(155)
      - No statistical differences in clinical improvement were detected between ruxolitinib (n = 20) and placebo (n = 21); however, the median time to clinical improvement was numerically faster for ruxolitinib (12 vs. 15 days; p = 0.147; HR 1.669; 95% CI, 0.836 to 3.335).
      - 80% of ruxolitinib (n = 16/20) and 71.4% of placebo (n = 15/21) developed adverse events by day 28. The 28-day mortality was 14.3% for placebo (n = 3/21), while no patients died in the ruxolitinib group.
    - Other JAK inhibitors for which COVID-19 efficacy data are being evaluated include tofacitinib.(132)
  - **Safety Concerns:** (92) (130) (131)
    - Thrombosis, including deep vein thrombosis (DVT) and pulmonary embolism (PE)
    - Risk of GI perforation
    - Caution in patients with neutropenia, lymphopenia, and anemia
    - Monitor for elevated liver function tests (LFTs)

**NSAIDs:**

- The NIH COVID-19 treatment guidelines recommend there be no difference in the use of antipyretic treatments (e.g., acetaminophen or NSAIDs) between patients with or without COVID-19. Patients taking NSAIDs for comorbid conditions should continue therapy as previously directed by their prescriber.(133)
• ESICM and SCCM Surviving Sepsis Campaign recommendations suggest acetaminophen for temperature control in critically ill adults with COVID-19 who develop fever.(26)
• The FDA continues to investigate the use of NSAIDs in patients with COVID-19 symptoms.(20)
• Concern for potential worsening of COVID-19 symptoms has been suggested, but confirmatory clinical data is lacking at this time.(5)
• There is an anecdotal published letter that suggests a link between ibuprofen and increased ACE2 expression that may lead to worse outcomes in COVID-19 patients.(50)

Nutritional Supplements:
• The role of nutritional supplements for the treatment or prevention of COVID-19 is unknown. Several supplements are under investigation in combination with other treatment modalities (e.g. zinc, vitamin C, vitamin D) for both treatment and prophylaxis.(111) (112) (113) (114) (115) (116) (117) (118) (119) (120)
• Due to insufficient data, the NIH COVID-19 treatment guidelines do not recommend for or against the use of vitamin C for the treatment of COVID-19.(133)
• Due to insufficient data, the NIH COVID-19 treatment guidelines do not recommend for or against the use of vitamin D for the prevention or treatment of COVID-19.(133)
• Due to insufficient data, the NIH COVID-19 treatment guidelines do not recommend for or against the use of zinc for the treatment of COVID-19. Guidelines recommend against the use of zinc supplementation above the recommended dietary allowance for the prevention of COVID-19, except in a clinical trial.(133)
• Safety concerns include adverse events from large doses and the potential for drug interactions.(108) (109) (110)
